ABSTRACT
The importance of human factors in road design and traffic safety has been undoubtedly increasing recently. As part of the human-centered design, schemata as mental representations induce road user expectations as well as trigger behavioral patterns. In road design this concept is called “self-explaining roads, meaning that road users automatically drive according to an expected behavior and speed. This requires different categories of roads, each with homogenous characteristics and a remarkable difference between them. This paper investigates how many unique categories road users are able to distinguish.

The paper first gives an overview of the design guidelines from a few countries highlighting the trends toward more self-explaining road networks. As a first step of the research, a picture-sorting task was completed to find out how road users group 45 different road scenes, and how these groups correspond to the road categories according to current design practice. In addition, a questionnaire survey was used to determine how individual road scene images are grouped on the basis of speed choice, and how this grouping corresponds to road categories. In both cases, cluster analysis was used to form and analyze the categories.

The main finding of both surveys is that road users have a limit in distinguishing road categories. This limit is not a strictly defined one, but it lies somewhere around 5 to 6. These results comply with the new guidelines in Germany and the Netherlands proving that the current initiatives to revise the Hungarian guidelines and the need for implementing the idea are justifiable.

Keywords: road category, self-explaining roads, road scene, driving speed
INTRODUCTION

Road networks are integrated in the transport system with two main interfaces between the drivers on one hand and the vehicles on the other. From an engineering as well as road accident administration point of view, it is generally accepted that driver-related factors are solely to blame for around 50% of accidents and that human factors are somehow involved in over 90% of the cases (1). From a psychological point of view this approach, however, does not differentiate between the latent failures (e.g. inappropriate driving speeds due to mistaken identification of road categories) and intentional actions (e.g. drinking and driving).

Accidents are the results of long chains of events. One cannot hope to reduce human error effectively without understanding the processes and conditions that cause such errors (2). Design of road infrastructure that neglects road user capabilities will result in latent failures. These failures adversely affect the psychological processes determining the behavior of road users. The human factor concept aims at reducing the probability of such failures.

A human-centered design and an integrated road traffic system considering human capabilities and limitations can minimize both the occurrence and consequences of human error (3). Several documents (e.g. 4, 5, 6) laid down basic safety principles of human factors. One of the possible ways to reduce the probability of human error in road traffic is to design clearly distinguishable road categories.

Perception can be based on two types of processes; top-down, or bottom-up. It is a well-established cognitive psychology model that was applied for instance by Rumar (7) to a driving task. Top-down processes play a key role in terms of anticipation. It means that the driver’s expectations depend on their past experiences. If the driver encounters a new situation, the more similar it is to a past situation, the stronger the expectations will be. These expectations are higher order representations of reality or schemata stored in memory. The activated representation depends on the perceived similarity of the actual situation with the characteristics of the situation stored in memory (8). Schemata help to increase efficiency in driver behavior, since giving clear indications or stimuli to activate a particular scheme will result in desired behavior. In road design, this concept is called self-explaining roads.

A self-explaining road is a traffic environment which elicits safe and consistent behavior among road users simply by its design (9). As a result, the road user is able to categorize a road and immediately know what sort of behavior is expected and the design, function and the use of the road will be coherent with each other. Another perspective on self-explaining roads is that drivers should perceive the maximum speed that a road safely affords. Three simple and basic principles of their design (9) are: easily recognizable, distinguishable and interpretable.

The effect of road width on driver speed choice depends on the amount of pavement the driver perceives as usable. This is affected by the lane width, number of lanes, shoulder width, presence of parked cars on the road edge, and presence of vertical elements on the roadside (10). Thus, cross-sectional layout is very important from the driver’s point of view regarding behavior during driving, for instance when choosing driving speed. In this study the cross-sectional layout of rural roads was investigated by means of questionnaire surveys and statistical tools.
SCOPE OF THE PAPER

This paper aims at answering two questions:

- How many road categories can road users distinguish by looking at their cross-section?
- How many road categories can be distinguished based on the stated speed choice of road users?

The first part of the paper gives a brief overview of the classification of roads according to design guidelines in a few selected countries (Hungary, Germany, USA, and the Netherlands). In order to answer the first question, a picture-sorting task and a cluster analysis were carried out. In the next phase of the research, a questionnaire survey was made to investigate the stated speed choice of road users. From the results, a cluster analysis was used to investigate whether the categories based on the speed choice comply with road categories set in the design guidelines.

CLASSIFICATION OF ROADS ACCORDING TO DESIGN GUIDELINES

Traditional road classification distinguishes a high number of road categories. The Hungarian road design guidelines define eight different design categories for rural areas and within each category there are additional 2-3 subcategories (I/1), so altogether 15 different types of rural roads can be designed. The difference between neighboring categories is marginal, e.g. the cross-section can be the same, and the alignment design parameters for example for design speeds 80 and 90 km/h are hardly different from each other. As a result, road categories cannot be easily distinguished from each other and the principle of self-explaining roads is lost. Hungary is not alone with this practice. Traditional road classification is still valid in most Central European countries, such as Austria, the Czech Republic, Poland, Romania and Slovakia.

In the US, according to AASHTO’s Policy on Geometric Design of Highways and Streets (I2), there are six rural and six urban road categories, including several sub-categories. The basis of the functional system is similar to the “traditional” Dutch road network classification (Figure 1, left side), where the relationship between travel mobility and needs for property access define the characteristics of highway facilities. Figure 1 shows the schemes of traditional and new road classifications in the Netherlands. On the vertical scale, the different road categories are marked, while the horizontal scale shows the share of the flow and access functions in these road categories.
FIGURE 1 Traditional (left) and new (right) road network classification in the Netherlands

It can be seen in Figure 1 that traditional classification distinguishes altogether eight road categories, while in the new classification there are only three. These categories are based on the concept of ‘sustainable safety’ distinguishing three categories in a network:

- roads with through function for rapid movement of through traffic;
- roads with a distributor function for the distribution and collection of traffic to and from different districts and residential areas;
- roads with an access function providing access to property whilst ensuring safety of the street as a meeting place.

In this system, considering both urban and rural areas, roads are categorized into only five categories. With the low number of road categories and sharp differences between them, the road conveys very clear information to the road user.

In traditional road classification, the road layout changes along a continuous curve from flow to access function and there is no sharp border between separate road categories. According to the new design philosophy it is much safer to apply fewer road categories with sharp and clear borders between them, so for the driver a uniform road design makes it easier to recognize, what function the road has and how they should behave.

Aarts and Davidse used a driving simulator and a picture sorting study to verify whether the “essential recognizability characteristics” of different road classes conformed to the expectations of road users (I3, I4).

In Germany, a new guideline for rural roads with significant changes to many aspects has been in force since May 2013 (I5). This guideline defines four rural road types (freeways are in
addition). Standardized roads mean that there are only a few, but unified road types. Individual
types should be distinctly different from the others. These two goals can be achieved if the
design parameters (alignment, cross-section, junction type, etc.) of individual road types are
determined using a narrow range of design values.

In order to allocate roads into road types, some quantitative characteristic is required as
the basis for categorization. Until now, this characteristic has been design speed. According to
the new German concept, the guiding parameter is the design class itself instead of design speed.

Design classes determine all design and operating characteristics, so the four design
classes on rural roads have their own

- cross-section;
- intersection type;
- curve radius range (both minimum and maximum);
- maximum longitudinal slope;
- crest and sag vertical curves;
- requirements concerning passing;
- access control for slow vehicles.

These characteristics are uniform within one design class, but sharply different between
classes. Speed is considered as an outcome of design.

Other countries seem to follow this trend: Denmark reported to decrease 17 types of
roads reduced to 5 (16).

**ROAD TYPES AND PICTURES USED IN THE SURVEYS**

The same nine road types were used in both surveys, considering the separation between
directions, number of traffic lanes and speed limit. Some of these categories (freeways,
expressways, rural roads, roads within built-up areas) together with their general speed limits are
well defined in the Hungarian Driver’s Manual. On these roads there are no speed limit signs, as
speed limit follows from the layout or from road type signs. For some other roads (like
categories 2, 3, 4 and 6 in Table 1), speed limits are posted. The latter are called “main road with
elevated speed limit” where the alignment of an already existing road was appropriate for a
higher posted speed limit. These roads are odd-men-outs in the system as there are just a few
hundred km-s of them. However they are important in the survey as there is a political pressure
to increase the length of such roads. There were also roads within built-up areas as well as road
scenes taken at the border of settlements named as transition zones. Road types and their main
characteristics are shown in Table 1.

For each road type 5 pictures, altogether 45 pictures were used. The photos were taken on
the same day, in bright weather, from the front right seat perspective, on tangent sections, in flat
terrain, with almost no traffic, no pedestrians, no bicycles in the pictures in order to concentrate
on the cross-sections and the surroundings.

CLASSIFICATION OF ROADS BASED ON CROSS-SECTIONAL LAYOUT

Picture sorting task

Applying a method used by Weller et al. (17), a picture-sorting task was performed using a sample of 104 persons. The respondents were all full-time university students and the test was part of their course exercise. This sample is clearly not representative of the Hungarian driver population, but the authors believe that the results are still useful for identifying differences between road types. Respondents received photographs of road scenes in printed form as playing cards with a description that was similar to Weller’s but with some changes applied.

The instruction was as follows. “You are about to see 45 pictures of roads; your task is to make a useful classification of these pictures. Try to imagine yourself driving on the road and ask yourself how you would behave or which behavior you would expect from other drivers on the same road. Sort pictures in such a way that the behavior on the roads in a group is the same, and different from behavior in other groups. You are free in choosing the number of pictures within each group and the total number of groups. When you are ready, write at least one - possibly more – key word for each group, which is typical for that group.”

The aim of the survey was to investigate how road users classify various road types and whether this distinction corresponds to road categories from our current design guidelines. Figure 2 shows that respondents most often formed 4 or 5 groups from road scenes. The number of persons with six clusters is also significant, but the ratio of those who made 7 clusters is only around 10%.

![Number of respondents depending on the number of groups chosen](image)

The term “speed” did not appear in the instructions, many of the respondents mentioned speed as a key word in some form. The most common term used for the description regardless of the number of groups chosen, was “road inside built-up area”, as well as “freeway” or “high speed”.

In addition to freeway pictures, respondents often added four-lane main roads with elevated speed limit to the group marked with the word freeway. Among the characteristics often
mentioned were “low, medium or high-speed”, “acceleration”, “reducing speed”, “braking” or “speed limit”. There were also some respondents who referred to “safety” or “accident risk”.

The following details are given based on the number of groups formed by the respondents.

Respondents, who formed three groups, typically used the following description for their clusters:

- freeway, high speed, acceleration, attention, routine, multi-lane, guardrail, uninterrupted driving;
- road outside built-up area, relatively fast, adequate attention, 2x1 lanes, worse pavement condition like on freeways, high traffic volume;
- road inside built-up area, increased attention, lower speed, slow, quiet, cyclists, pedestrians, speed restriction.

The four-group versions had two clearly separated groups with freeways and roads inside built-up area. The other two groups were formed in various ways; there were some who divided them into good and poor quality pavement roads, while others described groups as expressways and main roads. There were some who referred to the number of traffic lanes or roadside trees as group features.

When choosing five groups, traffic volume was mentioned, which was not typical for lower group numbers. Here visibility and presence of curves also appeared as an influencing factor. Typical descriptions were: a) freeway - expressway - main road - minor road - built-up area or b) freeway - high traffic volume - medium traffic volume - low traffic volume - built-up area. Some respondents referring to the number of traffic lanes and distinguished transition zones from urban roads formed the following groups: freeway - four lane road - two lane road - road in transition area – road in built-up area.

As for persons sorting the road scenes into six groups, categories according to the number of traffic lanes were typically further divided by presence or absence of physical separation between traffic directions.

Those respondents, who formed seven or even more groups, often mentioned overpasses or presence or absence of emergency lanes, in addition to the features mentioned above.

Cluster-analysis of groups formed

The groups formed were processed as 45x45 similarity matrices, where each cell indicates how many respondents put the particular road scenes into one category (as an example in Figure 3 road scene pictures number 4 and 7). This value ranges from 0 to 1 (normalized values), the closer this value to 1 is, the more respondents merge them into one category, the less is the “distance” among them.
FIGURE 3 A portion of the similarity matrix. These two pictures were put in the same group by 86% of the respondents.

Figure 4 shows two pictures from the collection which come from different categories. The left picture was taken on a motorway with 130 km/h speed limit and emergency lane, while the right picture on a dual carriageway road with 110 km/h speed limit, without emergency lane. In the survey, 63% of the respondents sorted these two pictures in the same category, which indicates that it is not easy to recognize the difference between these two road types.

FIGURE 4 Examples from the pictures shown
In the next step, the similarity matrix was used as an input for hierarchical clustering (in SPSS) using the agglomerative algorithm being a ‘bottom up’ approach where each observation starts in its own cluster, and then moving up the hierarchy pairs of clusters are merged. In the end we get one cluster, which contains all elements.

The results of hierarchical clustering are usually presented in a dendrogram, showing the merging process. If the tree is cut at a certain height, at that point the results of clustering can be interpreted. The dendrogram in Figure 5 shows an example for 5 clusters.

On the horizontal axis of the dendrogram each picture is marked with a number, on the vertical axis the rescaled distances of clusters are shown, horizontal lines show joined clusters. The position of these horizontal lines on the vertical scale indicates the distance at which clusters are joined.

Using the dendrogram cut with the thick horizontal line at five clusters, the following road categories can be identified (from left to right):

- highways with physical separation of the two directions (freeways, expressways)
- two lane expressways and two-lane roads with elevated speed limit
- four lane roads with elevated speed limit, without physical separation of the directions
- two lane roads
- urban roads and transition zones

**FIGURE 5 Dendrogram with five clusters**

Analyzing the percentage change in the average distances within clusters (Figure 6) a similar conclusion as before can be drawn, i.e. roughly over 5-6 clusters the change in the distances within clusters is marginal.
FIGURE 6 Change in the average distances within clusters

Some of the clusters that were formed contained heterogeneous roads in terms of their actual speed limits. This led us to the next step surveying what speed the road users would choose and how that relates to the categorization of roads.

CLASSIFICATION OF ROADS BASED ON SPEED CHOICE

The choice of speed by drivers mostly depends on the layout, the conditions of the road environment and the current traffic conditions (18). Different geometric parameters of roads have different effects on vehicle speeds (19, 20, 21). Some studies apply the “stated speed” method: respondents have to choose their driving speed according to road scene photographs, which are shown to them (22, 23). Similar to these studies, our analysis used a questionnaire survey to determine speed choice of drivers.

Questionnaire survey

In this web-based questionnaire, survey respondents had to review photographs of road scenes. The aim of the study was to explore how many road categories can be distinguished based on the speed choice. The sample consisted of 500 respondents of full and part-time university students as well as other respondents from the authors mailing list, with an average age of 30 years, 76% of the participants were male, 24% female. This sample is different from the Hungarian population of license holders in terms of age and gender, the average age being 47 years and the male/female ratio 58% - 42%.

Participants were asked to define what speed they would prefer for each road scene, but were not informed about the actual speed limit. The questionnaire consisted of the same 45 photographs used for the picture-sorting task in the previous chapter. There was almost no traffic in the pictures in order to estimate free-flow speeds. Respondents viewed a randomized sequence of photographs in order to rule out possible sequence effects. The time pictures were on the screen was not limited, but subjects could not go back to previous photos and see their ratings. Subjects provided the speeds in multiple choice system with 10 km/h steps.
Cluster analysis of roads based on chosen speeds

This study aimed at determining how individual images are grouped according to the chosen speeds and how this grouping corresponds to road categories.

The analysis was used for grouping of speed values given by respondents for each road scene image, the degree of similarity was the sum of differences between the coordinate data (squared Euclidean distance).

When forming two clusters, roads outside built-up areas and roads inside built-up areas together with transition zones are clearly separated. Dominant elements leading to the distinction of clusters are roadside buildings.

When making three clusters, (Figure 7) roads inside built-up areas and transition zones still remain together, but roads with and without physical separation at this point are separated according to speed choice. The most important influencing element was physical separation between traffic directions.

![FIGURE 7 Roads grouped into three clusters](image)

When dividing into four clusters (Figure 8), roads inside built-up areas and transition zones were allocated into separate groups, the main factor here is the densely or sparsely built-up roadside environment.

![FIGURE 8 Roads grouped into four clusters](image)
With five clusters, two lane and four lane roads with and without physical separation were not separated from each other. The same applies to rural roads and two lane roads with elevated speed limit of 110 km/h.

Even with six clusters, roads with and without physical separation remain grouped. As for seven clusters, freeways are quite clearly separated, as well as primary rural roads, so these roads are easily identifiable and recognizable by road users according to the speed choice. Roads inside built-up area and transition zones are also well separated, but two-lane and four-lane roads as well as roads with and without physical separation are mixed. Beyond seven clusters no clear description can be given to categories.

Table 2 shows that with growing cluster numbers the average distances from the cluster centers are decreasing, but the change is diminishing.

Based on the results of the cluster analysis the following conclusions can be drawn:

- Similar to the picture-sorting task, road users can only distinguish about 5-6 road types. Additional clusters cannot be clearly linked to road types.
- Some of these clusters comply with the road categories set in the guidelines and in the Driver’s Manual, for instance two-lane rural roads and freeways are good examples. In these cases the speed choice is also in line with the speed limit. These roads are self-explaining.
- Cross sections that are “interim solutions” such as two-lane roads with elevated speed limits cannot be clearly differentiated from other road categories by the road users. In these cases the speed choice of the road users is not in line with the posted speed limit, showing uncertainty in road user behavior.
- The fact that some roads are not properly grouped in the 5 or 6 clusters case, does not mean that 5 or 6 road classes would be appropriate. It simply means that due to some special road categories, classification starts to fail at these numbers.

**DISCUSSION AND CONCLUSIONS**

Even though the samples were not representative for the total driving population and the survey methods included simplifications, the results confirmed previous investigations that some road types are recognizable for road users while others cause uncertainty, that is, they are not
self-explaining. As uncertainty can cause risky situations, road users should be informed with special care about their expected behavior along these sections. According to the cluster analysis of road scenes, based on speed choice as well as the picture sorting task, the results are concurrent proving that road users have a limit in distinguishing road categories. This limit is not a strictly defined one but it lies somewhere around 5 to 6. These numbers are in harmony with the new German and Dutch classification. It is proposed to upgrade the Hungarian technical specifications, guidelines according to these principles. The revision of the Hungarian guidelines is currently underway, the above findings will most probably be considered. Further research could consider a wider sample of roads, including minor roads, curves, hilly terrain, traffic and other factors.
