The 96th Annual Meeting of the Transportation Research Board,
Washington D.C., January 2017
ABSTRACT
The ability to walk or ride a bike safely to and from metro stations is essential to the success of any metro service, especially if some of these activities are from car users switching to the service. The main purpose of this study is to develop and apply a simple method to be used to assess, compare, and rank the walkability around different metro stations and develop a priority order and specific recommendations for improvements. The proposed method depends on extracting the walkability variables in the catchment areas around the metro stations. Three catchment areas around three proposed metro stations in the emerging city of Doha, Qatar were investigated using the proposed method to demonstrate its usefulness. The method was successful in comparing and ranking the different catchment areas in addition to identifying priority areas for walkability enhancements in each area. This method is simple and can benefit professionals, practitioners, and policy-makers to make fast decisions for future corrective measures, and it can also be used to evaluate changes over time.

Keywords: Transit-oriented development, Public transportation, Transit stations, Urban design, Bus stations, Accessibility
INTRODUCTION

Access to the metro stations is extremely important for the success of any rail based transport system and will play a major role in shaping the future of the use of the metro system, especially in areas with high potential of travelers, dense housing, high number of workplaces and attractions in addition to shopping areas, sports facilities, and entertainment areas. Most of the travelers in public transport systems come from areas in the vicinity of the station. These areas are called the catchment areas and can be defined as the vicinity of a station of public transportation where most of the transferring passengers at the station come from. Thus, the streets surrounding the transit stations must support multiple transportation modes such as buses, pedestrians, and bicyclists from different principles for all users (1).

Applied analysis of catchment areas for public transport can serve different purposes. They are usually used in the planning process of new public transportation services. Catchment area analysis can serve in the initial phase when the stop has to be placed on a new line. More detailed catchment area analyses can be used to investigate improvements in the accessibility of stations. Such improvements result in a Transit-oriented development (TOD). TOD is a development design with the main goal of promoting walking, biking, and the usage of transit as feasible transportation choices in a neighborhood. TODs play a major role in increasing the transit ridership. This case happens when more people switch to transit, especially car-users, which will reduce the number of vehicle miles, promote healthier behavior, reduce congestion and greenhouse-gas emissions. This switch will also result in a significant savings for the car-users due to not using their private car for transportation (2) in addition to healthier habits and improvement in obesity and other health problems (3).

Research showed that TOD oriented neighborhoods have less traffic congestion compared to other neighborhoods (4). Studies also showed that the best method of assessing TODs is to evaluate the walkability in these neighborhoods (2, 5, 6). This type of assessment is understandable because improving walkability in a neighborhood provides pedestrians with better access to the transit stations. This improved access would encourage more people to use transit in return. Research also showed that improving walkability can also encourage pedestrians to walk to transit stations from a cost-benefit point of view (7).

In order for TODs to be successful, walking and biking are encouraged within a quarter or a half a mile from the transit station (5, 8). This is the same concept used in public health research where walking conditions are improved for pedestrians to reach the different amenities in a neighborhood by walking. In this type of research, a walking score is used to measure walkability and accessibility in a neighborhood (9). In some cases, it is also used as a factor to compare the accessibility of a house when buying real estate (10). This study is mainly focused on investigating the connectivity of sidewalks and the walking environment in the catchment areas around the three upcoming metro stations in the city of Doha, Qatar.

DOHA METRO NETWORK

Qatar, a fast-growing country in the middle east, is facing an unprecedented challenge to deal with rapid growth within the country constrained by high demand on the existing road network and the high usage of private cars for transportation. The number of daily trips per day in Qatar increased from 1.7 million trips per day in year 2000 to 5.5 million trips per day in 2012. The
existing bus service, which is the only public transportation in Doha is limited. A total of 27
internal bus lines run within the city of Doha and 14 external bus lines connect Doha to other
remote cities. Bus service frequency varies from 30 minutes to 1 hour, which seldom attracts
those on higher incomes to use the bus services. Due to the infamous traffic congestion in Doha,
buses often do not arrive at stops on time, particularly during rush hours. Thus, taxis are used
more as a means of transportation than buses. To address the fast-growing demand on the
transportation network, the Qatari government is currently building the first metro system in
Doha. The metro’s first phase is expected to be completed in 2020 to be ready for the Qatar 2022
FIFA World Cup, while the final phase is expected to be completed in 2026. The metro network
is designed to link all the major town centers, major commercial and residential areas, Olympic
venues, villages, hotel's district, and the New Doha International Airport with four lines and 100
stations with a total length of approximately 360 kilometers (11-15).

To benefit from the new metro service in reducing traffic congestion in Doha, the metro must
attract sufficient commuters, including regular transit users and individuals who have the option
of commuting by car. The more people switch to transit, the more benefit it will be to the
mobility inside the city. Access to the proposed metro stations is needed to ensure the success of
the system under construction. Most of the travelers in public transport systems come from areas
just around the station. In order to promote walking and biking, the streets surrounding the transit
stations must support different modes including buses, pedestrians and bicyclists. Therefore, a
simple evaluation method was needed to assess, compare, and rank the walkability around these
different metro stations.

**METHODOLOGY**

The proposed evaluation method used in this analysis focuses on analyzing the sidewalks, bike
lanes, parking spaces, and bus transit service within the station's catchment areas. This
evaluation will assist in identifying the impact of those elements on the accessibility of the metro
stations and consequently proposes any needed improvements. This type of assessment will lead
to improvements that can reduce traffic congestion, need for parking, and savings for the users,
especially among car users who would be otherwise driving. These improvements if combined
with high-quality public transportation can help in direction the car users to the use of the metro
stations (16).

In this study, the circular catchment area approach was used, which is based on investigating a
catchment area within a circle radius of a half-mile range (800 meters) from the metro stations.
This value is the high limit of the range recommended of the quarter to half a mile from the
transit station by previous studies (5, 8, 17, 18). This approach is the simplest approach and most
used compared to the service area approach, which is based on searches in road networks to find
the actual feeder routes (19).

In this approach, the catchment area is split into three different circular levels. The first level is
the core station area, which is defined as the direct area around a transit station within which the
land use and urban design features have a main effect on the system ridership. In this area,
pedestrians access generates an extremely significant portion of transit trips to and from the
station. The second level is the primary catchment area (200 meters circle around the transit
station), which is defined as the area within which the land use, urban design features, and the
ease access to the station have a considerable impact on the ridership. In this area, pedestrian
access generates a significant portion of transit trips to/from the station. Finally, the third level is secondary catchment area (800 meters circle around the transit station), which is defined as the area around a station within which ease and directness of access to the station have the greatest influence on the ridership. In this area, bike, feeder system, and passenger cars, including taxis are the primary access modes to and from the station. The method developed in this study evaluate the catchment areas based on different criteria including the availability of sidewalk, bike lanes, pedestrian/cyclist friendly intersections, parking spaces; and bus stops. These elements are listed in FIGURE 1.

![Evaluation Elements](image)

**FIGURE 1 Evaluation Elements**

**Availability of Sidewalks**

In the proposed method, the availability of sidewalks on a road segment is based on having proper sidewalks available on both sides of the segment. Therefore, for a given length of a road segment, the length of the existing sidewalks should be approximately twice the length of the road segment. This approximation was used to simplify the calculations since the main purpose of the developed method is to compare and rank the catchment areas for different stations. A more detailed method would be to deduct the width of the intersections from the total length of the road segment as the road interrupts the sidewalk at each intersection. The definition of a proper sidewalk in this study was based on having a minimum width of 1.8 meters according to the Qatar Highway Design Manual (20) and as illustrated in FIGURE 2.
Typical cross section showing minimum sidewalk width of 1.8 meters

Typical cross section showing minimum shared sidewalk width of 3.0 meters

Typical cross section with on-street parking

FIGURE 2 Typical Section Showing Minimum Sidewalks and Parking Widths

Source: Qatar Highway Design Manual (20)

TRB 2017 Annual Meeting

Paper revised from original submittal.
Availability of Bike Lanes
The availability of bike lanes on a road segment in the proposed method is based having proper bike lanes both sides of an existing road. Therefore, for a given length of a road segment, the length of the existing bike lanes should be approximately twice the road segment. A proper bike lane is defined as a dedicated, marked, and properly signed bike lane, a sidewalk that is wide enough to accommodate both the sidewalk and the bike lane, or a wide paved shoulder that, while not marked for bicycles, might serve as a de-facto bike lane. The width of the sidewalk shall not be less than 3.0 meters to be considered as shared sidewalk as illustrated in FIGURE 2 and per the Qatar Highway Design Manual (20).

Availability of Pedestrian-Friendly Intersections
All intersections in the catchment areas were evaluated based on four levels, which include (1) having no crosswalks, (2) having crosswalks on some approaches, (3) having crosswalks on all approaches, and (4) having crosswalks on all approaches and pedestrian signals. For the purpose of this evaluation method, an intersection is considered pedestrian friendly if it has crosswalks on all approaches or had crosswalks and pedestrian signals.

Availability of Bus Stations
Only bus stations that are available within the primary catchment area (200 m) from the metro station were considered in this analysis. In the case of having multiple transit bus stations for the same bus lines in the same catchment area, only the closer one to the metro station entrance was considered assuming that the bus passengers will choose to disembark at the closer station. Hence, the calculations omitted the farther bus stations.

Availability of Parking Spaces
On-street parking was considered only if the parking was legal and safe to park. Otherwise it was considered a private parking. For example, parking spaces located in front of residential houses or private properties were not considered in the analysis. Also, existing road shoulders were not considered as on-street parking. Parking spots within local roads that are mainly occupied by the residents of the local road were also not included in the analysis due to the fact that it will be used mainly by the local residents. However, parking spots within main roads were considered as potential parking spots for the metro users. When accounting for the on-street parking, it was assumed that the length of a car parking spot is 6.0m in length in accordance with Qatar Highway Design Manual (20). It should be noted that on-street parking is available only in the form of parallel parking in the City of Doha. Also, there is no cost or time limits applied to the use of these type of parking spaces.

The availability of public parking lots within the catchment area was also taken into consideration and added to the number of parking spaces. For these public parking lots to be considered in the analysis, the parking lot must be public, properly designed, paved, marked, signed, and designated for general public use. A parking lot that cannot be accessed or is dedicated for a specific use such as a mall or a shopping plaza was not included in the analysis.
Overall Catchment Area Evaluation

An assumption was made that each factor should be included equally in the overall evaluation. This assumption may not necessarily represent the overall performance of the catchment area accurately. Some factors may be more or less important than the others depending on public agency's preference. This issue should be investigated further in order to provide a realistic evaluation of the catchment area. It should be noted that areas under construction were evaluated based on the way the road is shaping up to. All formulas used for the calculations are shown in TABLE 1.

DATA COLLECTION

Three catchment areas around three under construction metro stations were selected for the analysis of this study. These stations are Al Waab station, Al Sadd station, and Doha Exhibition and Convention Center (DECC) station. The Al Waab and Al Sadd stations are located along the Golden Line, while DECC station is located along the Red Line as shown in FIGURE 3. The three stations were selected in a way to cover different types of land use. Detailed land use maps for the three stations are shown in FIGURE 4. Road names and locations were collected from the Center of Geographic Information System of Qatar (CGIS) of the Ministry of Municipality and Environment (MME) website. Site visits were conducted, and the data was collected and documented in spreadsheets. A summary of the data collected is shown in TABLE 2. Moreover, FIGURE 5 shows a sample of the different observations collected in the field.

Doha Exhibition and Convention Center (DECC) Station

This metro station is located with densely developed area. The land use is mainly office towers, residential towers, hotels, commercial buildings, exhibition center, schools, and mixed-use buildings. This area is considered as the Central Business District of Doha. Most of the roads and infrastructure within the catchment area of the DECC station are newly constructed. These roads have sufficient and proper sidewalks. In the majority of the roads, the sidewalk is wide enough to accommodate both sidewalk and bike lanes. The sidewalk is connected through proper crossing at the intersections. The area is served by a shuttle bus service that covers most of the catchment area. The area also have many public parking lots located near the station. These parking lots may encourage the ridership of the metro station, as many of the drivers will be encouraged to park their vehicles and use the metro.

Al Sadd Station

The land use around the Al Sadd station has office buildings, multi-family residential buildings, hotels, commercial buildings, mixed-use buildings, and schools. The area is densely developed, and most of the local roads are old and designed without accommodating sidewalks, bike lanes or parking. Most of the major intersections have proper signalized crossings. However, the minor intersections were not properly designed or constructed to accommodate the pedestrian/cyclist crossings. The station area is partially covered with bus service. The majority of the bus stops are poorly designed. Most of the main roads had on-street parking. However, most of the local roads are too narrow and were not proper to accommodate on-street parking.

Al Waab Station

The land use around the Al Waab station is mainly single-family residential buildings, shopping areas, and schools. This station has a direct connection with Al Waab Street, which is well-designed and constructed. This road has dedicated and continuous bike lanes and sidewalks on both sides of the road. The continuity of the sidewalk and the bike lanes is maintained through signalized crossings at all the signalized intersections. On-street parking is available and properly designed along Al Waab Street. Several bus stops are located along around the station. The major intersections in the catchment area are properly designed to accommodate pedestrians and cyclists’ movement. Other than the main streets, most of the local roads did not have sidewalks, bike lanes, or on-street parking and the intersections are designed to handle pedestrian and cyclist.

ANALYSIS AND RESULTS

By applying the formulas listed in TABLE 1, it is evident that both Al Sadd and Al Waab stations scored lower than the DECC station for the set evaluation criteria. The sidewalks and bike lanes were unavailable in most of the roads in both catchment areas. Most of the intersections did not have proper crossings, which result in a lack of connectivity. The DECC station has shown better scores since most of the roads within the catchment area are newly constructed. Proper and wide sidewalks that can easily accommodate bike lanes are available in this catchment area. In addition, the area is served by a shuttle bus service. In the overall evaluation, it is not the case when one catchment area scores well in one category means that it will score well compared to the other catchment areas. A balance between the different categories is needed in order to have a high score. FIGURE 6 shows the strength and weakness of each catchment area.

FIGURE 6 Evaluation Results for the for the Catchment Areas
FIGURE 7 Features of the Catchment Areas for the Catchment Areas
To achieve a better understanding of these rankings, a visual-spatial analysis is shown in Figure 7. The GIS-derived maps give a visual analysis of the different studied elements, which makes it easier to identify locations with problems and areas in need of improvements.

CONCLUSIONS AND FUTURE WORK

In this study, a simple method was developed to assess walkability around metro stations in the city of Doha. The data for three catchment areas around three metro stations under construction including intersections, sidewalks, bike lanes, bus stations, and parking availability were collected and used to evaluate the proposed method. The method was effective in evaluating and ranking the studied locations and can be used to evaluate more stations as needed. The method is easy, simple, fast, and effective. All walkability elements were assigned the same weight. The method can easily be modified to assign different weights for the different elements as needed.

This type of assessment can be useful for urban designers, urban planners, transportation planning professionals, as well as policy-makers and practitioners. It can help to identify priority areas for enhancements and improvements, and it can be applied to track changes and improvements over time. Moreover, it can be used to investigate policies, develop funding plans, and discussing options and alternatives with stakeholders to increase and promote safe walking and bicycling around transit stations. Furthermore, this method can be useful in conducting a fast and simple evaluation during the planning phase of any proposed transit to assist with selecting the best location for the transit station for walking and biking activities.

It is important to note that this study has limitations that could be possible avenues for future research. One of them is related to focusing on availability only. For example, the condition of the sidewalk was not taken into consideration. For example, cracks, broken sections, and debris can impact the usage of the sidewalks. Similarly, the significance of one side of the sidewalk over the other was not considered. For example, the sidewalk on the side of the metro station entrance can be more important than the other side. In addition, special conditions such as having shared zones (pedestrians, cyclists and vehicles share the same road space) or shared lanes (cyclists and vehicles share the same road space). Taking these factors into consideration should be investigated. Also, the analysis of parking did not include factors such as the cost and time limits that may be applied to use of the parking spaces since they do not currently exist in the City of Doha for off-street parking. These factors should be taken into consideration if available.

Furthermore, the proposed method focused on identifying infrastructure issues as impediments to the use of walking, biking, and public transportation. However, the impact of additional factors such as the population, density, and land use of the catchment area should be considered because they can play a major role in the success of TODs. Also, it will useful in the future to link the developed walkability evaluation index with other performance measures such as the station ridership or the percentage of people in the area using public transit. Finally, the method did consider the impact of weather on the walkability in the catchment areas, which should be considered in future research. The weather in the city of Doha is hot especially during summer where the average daily temperature can reach 50 °C or more, with fairly high humidity. A previous study in the city showed that the weather along the year has a significant impact on the pedestrian volumes (22). Given the high level of comfort in a private vehicle versus the walking alternative, this factor may impact the efforts to induce a person to walk.
